ABSTRACT

Superficial folliculitis is the result of inflammation of the terminal part or ostium of the hair follicle due to infective or non-infective origin. It affects mainly young adult males in India. Clinically characterized by profuse eruption of superficial pustules, predominantly affects the lower legs without any systemic disturbances. It runs a chronic recurrent and relapsing course usually resistant to treatment. The present work is undertaken to study the clinical and epidemiological pattern of the chronic superficial folliculitis of the legs.

MATERIALS AND METHODS

The study was carried out on patients attending the Outpatient Department of Dermatology, King George Hospital, affiliated to Andhra Medical College, Visakhapatnam, for a period of 1 year. It is a prospective study and a total of 100 cases were studied.

RESULTS

In this study, most common age group is in between 20-29 years. Males (95%) outnumbered females (5%) by the ratio of 19:1; 50% were casual workers, 95% presented with lesions with bilaterally symmetrical distribution affecting both the lower legs; 50% had mild pruritus, 67% showed exacerbations of recurrences during summer; 14% had history suggestive of atopy. In 85% gram stain, examination of the smear from the lesions showed Staphylococci. On culture, coagulase positive staphylococci were isolated from the lesions.

CONCLUSION

In the present study, superficial folliculitis of legs most commonly affects young adult males, classically involving the anterior aspect of lower legs. Most common causative organism is Staph aureus.

KEYWORDS

Superficial Folliculitis, Follicular Pustules.

INTRODUCTION

Superficial folliculitis is the result of inflammation of the terminal part or ostium of the hair follicles. It may be of infective or non-infective origin.

Chronic superficial folliculitis of legs affects mainly young adult males in India. It is clinically characterized by profuse eruption of superficial and deep follicular pustules. It most commonly affects the lower legs followed by thighs. Individual lesion is dome shaped yellow pustules with central hair. Sometimes the lesions are surrounded by erythema; it persists for many years and is usually resistant to treatment. Recurrences are usually common during summer. There are no systemic disturbances. Sometimes hypergammaglobulinaemia may be present. It is usually asymptomatic, sometimes pruritus may be present. During acute attacks, pain may be present.

were done and the strains were tested for the production of coagulase to know whether the strain isolated was pathogenic or non-pathogenic.

RESULTS

100 patients presenting with superficial folliculitis were included in the study and all parameters were evaluated. Most common age group affected is in between 20-29 years (41%) and 30-39 years (29%); 95% were males and male-to-female ratio is 19:1; 50% were casual workers followed by farmers; 67% have exacerbations during summer; 50% has pruritus and 30% had pain; 95% of cases showed bilaterally symmetrical distribution of lesions affecting both the lower legs. In all patients, involvement of lower legs is seen. In addition thighs were effected in 22%, forearms in 12% of cases.

Direct microscopic examination of Gram stain showed Gram positive cocci in 80% of cases. In all cases, coagulase test was positive. Mannitol fermentation is positive in 82%. Phenolphthalein test is positive in all cases. Salt agar test is positive in 80% cases. Majority of strains belong to phage group III and phage type 83A.

DISCUSSION

The present study deals with the clinical and epidemiological study of 100 cases of chronic folliculitis of legs attending the Outpatient Department of KGH, Visakhapatnam.

Age

In the present study, the commonest age group affected was 20-29 years (43%) followed by 30-39 years (30%). This is in agreement with the previous studies conducted by Wright RC in 1992[1] and Desai SC et al in 1964[2] who also reported that chronic folliculitis of legs mainly affects young adults. Dr. PVS Prasad in 1997 reported 48% of patients in the age group 16-25 years[3].

The high incidence among males may be due to the fact that males are more involved in manual labour and exposed to factors which may predispose to chronic folliculitis.

**OCCUPATION**

Majority of patients in the present study were casual workers; 50% in various occupations like stone cutting units, cycle shops, garages followed by farmers (16%).

Exposure to various material like stone dust, machine oil may account for the high incidence of chronic folliculitis in casual workers. Dr. PVS Prasad in 1997 reported 44% patients were agricultural labourers. [3]

Higher incidence in farmers may be due to contact with mud and pesticides causing disruption of barrier function resulting in infection. (TABLE 2)

**Seasonal Variation**

Majority of cases (67%) showed exacerbations of recurrences during summer. Similar seasonal aggravation reported by Sugathan P et al [4] in 1973. They reported aggravations in summer in 50.6% of cases. Aggravation was also reported due to factors like contact with mud, oil, stone dust. Similar aggravation factors were also reported by S Jacob Zacariah et al in their study in 1973. (IMAGE 2)

History suggestive of atopy reported in 14% of cases. Predisposition to staphylococcal infections in atopic individuals may be the reason for the high incidence of atopy reported in the present study. Leydon JJ, Marples RR, Klingmann AM in 1974 reported high number of S. aureus in atopic eczema.

Mild pruritus reported in 50% and pain during acute attacks in 30%. Dr. PVS Prasad in 1997 reported pruritus as the predominant symptom in 86% patients. [3]

Lower legs affected in all 100 cases. In 28%, lesions are confined to the lower legs; 22% had lesions on front of the thighs in addition to legs and in 12% forearm also involved in addition to legs and thighs. (TABLE 4)

On direct smear examination after gram stain, clusters of staphylococci were seen along with plenty of pus cells in 80% of cases. Only pus cells seen in 20% may be due to technical error.

**Biochemical Tests**

All strains isolated from lesions were shown to be coagulase positive, mannitol fermentation was reported to be positive in 82% of cases.

**Phage Typing**

Majority of the strains were not typable with the set of phages employed. Of the typable strains, majority belonged to phage group III (B). Most prevalent phage type was group III (A). Similar observation reported by Pasricha et al. [5]

**CONCLUSION**

Chronic folliculitis of leg runs in chronic recurrent and relapsing course. Most commonly affecting the young adult males. Classical sites are lower legs followed by thighs usually show exacerbation of lesions in summer. Predominant symptom is pruritus. Commonest organism is phage group IIIA coagulase positive staphylococcus.
