HOW TO CITE THIS ARTICLE:

ABSTRACT: AIM-To diagnose radix paramolaris with the aid of spiral CT which often gets misdiagnosed in routine radiographic imaging to increase success rate of root canal treatment.
SUMMARY: An additional mesio-buccal root, the radix paramolaris is major anatomical variant of the two rooted mandibular first molar. Awareness and understanding of this unusual root morphology contributes to the success of root canal therapy. This case report provides insight into the endodontic management of mandibular molar with radix paramolaris, with the aid of spiral computer tomography. The canals were shaped with hand protaper files and irrigated with 5.25% sodium hyochlorite, 0.2 %w/v of chlorhexidinegluconate and normal saline as the final irrigant. The canals were then obturated with gutta-percha and AH plus sealer. This case report shows an anatomic variation of internal morphology of the tooth and points out the importance of searching for additional canals and roots.
KEYWORDS: Radixparamolaris, spiral computed tomography, mandibular first molar.

INTRODUCTION: An awareness and understanding of the presence of unusual root canal morphology can contribute to the successful outcome of root canal treatment. It is known that the mandibular first molar can display several anatomical variations. Commonly the mesial root has two root canals, ending in two distinct apical foramina. Sometimes these merge together at the root tip to end in one foramen. The distal root typically has one kidney-shaped root canal, although if the orifice is particularly narrow and round, a second distal canal may be present. The number of roots may also vary1.

The prevalence of these three-rooted mandibular first molars appears to be less than 3% in African populations, not to exceed 4.2% in Caucasians, to be less than 5% in Eurasian and Asian populations2, and to be higher than 5% (even up to 40%) in populations with Mongolian traits3 and 5.97% in Indian population. An additional third root, first mentioned in the literature by Carabelli (1844), is called the radix entomolaris (RE) when it is present lingually and paramolaris when it is present buccally4. The study of root and canal anatomy has endodontic (Vertucci 1984) and anthropological (Tratman 1950, Dahlberg 1965, Walker 1988a, b) significance5. It is important to be familiar with variations in tooth anatomy. With advent of Dental CT and Cone beam computed tomography (CBCT) the shortcomings of conventional imaging are overcome as they provide accurate and specific information. Dental CT with dedicated post scanning image evaluation software used for the teeth and the jaw creates panoramic and paraxial views of the upper and lower jaw6-7. Dental CT provides adequate life-size visualization of osseous anatomy, with no streak artifacts of restorative material and a lower radiation dose compared with conventional CT.
CASE REPORT: A 25-yrs male reported with the chief complaint of pain in the left mandibular tooth to the Amrutvahini hospital, Sangamner. On clinical examination the tooth was grossly decayed and radiographically the unusual root pattern seen with mesial root Fig A. To ascertain this complex root anatomy spiral CT was planned. The spiral CT was performed at Sai Baba Hospital Shirdi. The CT scan machine used was Seimens Somatom Sensation 64 which had multidetector technology with 32 detectors and 64 data channels. Scan direction was caudocranial beginning with the mandible base and extends to include the alveolar crest. Slice thickness of the images was adjusted to 0.5 mm with slice interval of 2mm. Tube current is 90mAs, tube voltage is 120, and table pitch is 0.9. Multiplanar reconstructions based on the dental CT protocol were obtained in the orthoradial and panoramic plane by using a dental software package (Syngo Dental CT 2006 A-W VB20B-W) on a workstation Fig. B with buccal view and Fig.C with lingual view. The 3 D reconstruction shows an additional root mesio-buccally with unusual morphology. After application of rubber dam, access was gained to the pulp chamber fig D. The coronal necrotic pulp tissue was removed and the chamber irrigated with 5.25% sodium hypochlorite solution (Comet India ltd). On close inspection of the pulp chamber, four distinct canal orifices, two mesial & two distal, were found. Initial negotiation of the root canals was performed with an ISO 15 No. K file. The different access inclinations between the two mesial canals, indicated the presence of two separate mesial roots. The lengths of these canals were measured radiographically and verified using apex locator (Dentaport, J Morita) Fig E. The canals were cleaned with sodium hypochlorite solution (5.25%) and Glyde (DentsplyMaillefer), and shaped with hand ProTaper instrument no. F2 (Dentsply Maillefer). All canals were filled with gutta-percha and AH plus sealer. Post endodontic restoration done with composite restorative material Fig F.

DISCUSSION: The etiology behind the formation of the radix paramolaris and entomolaris is still unclear. In dysmorphic, supernumerary roots, its formation could be related to external factors during odontogenesis, or to penetrance of an atavistic gene or polygenetic system. The presence of the Radix paramolaris or the Radix entomolaris has clinical implications in endodontic treatment. Radiograph and interpretation of particular marks or characteristics, such as an unclear view or outline of the mesial root contour or the root canal, can indicate the presence of a ‘hidden’ Radix paramolaris. Slowley (1974) has demonstrated how difficult it is to detect extra roots, let alone extra canals. On the contrary, completing a thorough radiographic study of the involved tooth with exposure from three different horizontal projections, the standard buccal-to-lingual projection, 20° from the mesial, and 20° from the distal reveals the basic information regarding the anatomy of the tooth in order to perform endodontic treatment (Ingle et al. 2002).

To reveal the Radix paramolaris, a second radiograph should be taken from a more mesial or distal angle (20 degrees). This way an accurate diagnosis can be made. Dental CT has about eight times higher resolution than the medical CT. Therefore, this device is thought to be useful for the examination and diagnosis of hard tissues of the maxillofacial region including teeth, alveolar bone, and the jaws. Intraoral radiographs are a two-dimensional imaging modality of a three-dimensional structure.

Hence anatomy in the third dimension cannot be assessed on radiographs. Because root canals tend to lie one behind the other in buccolingual plane, they get superimposed onto each other on periapical, panoramic radiographs and easily go undetected. Predictably successful root canal treatment is dependent on following the basic principles: access, cleansing and shaping, and
obturation of the entire root canal system. These principles have evolved from clinical concepts established through clinical practice and basic research\textsuperscript{17,18}.

CONCLUSION: Preoperative periapical radiographs exposed at two different horizontal angles are required to identify these additional roots. Knowledge of the location of the additional root and its root canal orifice will result in a modified opening cavity with extension to the mesiobuccal. The morphological variations of the Radix paramolaris in terms of root inclination and root canal curvature demand a careful and adapted clinical approach to avoid or overcome procedural errors during endodontic therapy.
