HOW TO CITE THIS ARTICLE:

ABSTRACT: The clinical course of anaesthesia during surgical resection of a pheochromocytoma of size 128 x 115 x 92mm is reported. Hypertension, hypotension, hypoglycaemia, hypovolaemia and a single attack of convulsion were observed and managed by appropriate pharmacological intervention and fluid replacement. Both spinal and general anaesthesia were used. Recovery of the case was good.

KEYWORDS: Pheochromocytoma, spinal and general anaesthesia, Hypertension, Pharmacological intervention.

INTRODUCTION: Pheochromocytoma, the catecholamine secreting tumour, mainly arises from adrenal medulla. The incidence of this tumour is around 1.5–2.1 per million population per year.¹² “Rute of 10” is an important feature of this tumour as 10% are bilateral, 10% are extra–adrenal, 10% undergo malignant changes and 10% are associated with various familiar disorders. The clinical features are hypertension (65% paroxysmal and 35% sustained), headache, vomiting, palpitation and episodic sweating. The main organ systems involved are cardiovascular (Arrhythmias, dilated cardiomyopathy, peripheral vasoconstriction and cardiac failure), central nervous system (Anxiety psychosis and nervousness) and hypermetabolic state causing weight loss. Cardiac failure, acute pulmonary oedema, fulminant toxemia during pregnancy and metabolic acidosis are the principal complications.

Unpredictable and fluctuating clinical features may occur during anaesthesia and surgery while dealing with this tumour. Hence, before surgical resection, the pre-operative preparation, pharmacological intervention and cardiovascular optimisation should be adequate. Adrenergic crisis occurs during induction of anaesthesia, laryngoscopy and intubation and also during tumour manipulation. To overcome this hazardous situation, adequate control of blood pressure and heart rate and correction of hypovolaemia are important.

CASE REPORT: A 32 years old female was admitted in the female Surgery Ward of I.M.S and Sum Hospital, Bhubaneswar, Odisha with the chief complaints of headache, palpitation, vomiting and paroxysmal hypertension with an abdominal swelling of 1 year duration. The CT scan of abdomen revealed a retroperitoneal cystic mass with asymmetric wall thickness of size 128x115x92mm behind the pancreatic tail with shifting of the left kidney inferiorly and pancreatic tail anteriorly; left adrenal not seen separately from the mass and no abdominal lymphadenopathy. Laboratory parameters were VMA (Vanillylmandelic acid) 43.90mg/24 hour (Normal 1.6–7.5), serum cortisol 36.50 micro mg/dl (Normal 2.3–11) and fasting plasma sugar, serum sodium, serum potassium, serum chloride, blood urea, serum creatinine with CBC (Complete blood count) within normal range. The case was diagnosed as pheochromocytoma. Echocardiography, ECG and chest X-ray were normal.
Pre-operatively she was treated for hypertension with different antihypertensive drugs (Telmisartan with amlodipine, prazosin and metoprolol) for 18 days. After control of blood pressure and heart rate (BP 140/98mmHg and heart rate 88 beats/minutes on the day before surgery), the patient was taken up for surgery with written consent. Preoperative check-up showed a blood pressure of 130/80mmHg and heart rate of 80 beats/minutes.

At the outset spinal anaesthesia was administered by using 3ml of 0.5% Bupivacaine and 180 microgram of morphine. The patient was oxygenated at a rate of 10 l/min for 3 minutes. After that the case was premedicated with 0.2mg Glycopyrolate, 2mg Midazolam and 100 microgram Fentanyl. Induction was done with 120mg Propofol and 6mg Vecuronium was used as muscle relaxant. Another 1mg, 2mg and 2mg vacuronium were administered intermittently for muscle relaxation. The case was put on BAG and MASK ventilation for about 3 minutes and 15 seconds before intubation with endotracheal tube. After intubation, the patient was shifted to ventilator mode. The volatile anaesthetic agent isoflurane was used with MAG-I and N2O: O2 of 2:1 and maintained with IPPV.

Arterial line was placed on the left arm for continuous monitoring of blood pressure and central line catheter was placed in Right subclavian vein for monitoring of central venous pressure and drug delivery. The antihypertensive drug labetalol was administered intermittently (Total dosages were 45mg–5mg+5mg+5mg+5mg+10mg+5mg+5mg) and sodium nitroprusside was used for 1 hour and 15 minutes. Phenylephrine at a dose of 50 microgram was needed once during the procedure. The other drugs used during the course of anaesthesia were 100 mg hydrocortisone, 8 mg Dexamethasone, 1 mg Butaphanol, 200 mg Phenytoin Sodium and 2 litres of Ringer Lactate with 500 ml of 5% Dextrose with normal saline. The patient was put for 24 hours in the observation room where the blood pressure and heart rate were within normal limits and thereafter she was shifted to the ward. The patient was cured and discharged after 12 days.

**DISCUSSION:** The present case had the clinical features of pheochromocytoma, e.g. headache, vomiting, palpitation and paroxysmal hypertension. The VMA was raised. The C.T. Scan of abdomen showed the accurate size and extension of the mass. For the first 18 days, the blood pressure was controlled adequately by the cardiologist. During anaesthesia and surgery, the blood pressure and heart rate were maintained within normal by using various antihypertensive drugs. The oxygen and fluid and electrolyte balance were maintained.

Anaesthesia and surgery of Pheochromocytoma carry a mortality rate of 50% in unprepared patients. However, the mortality was reduced from 13–45% to 0-3% after meticulous use of alpha-adrenergic blocking drugs and well correction of hypovolemia. In the present case, we used appropriate antihypertensive drugs and volume was corrected by using fluids. We used a combined spinal and general anaesthesia as mentioned in earlier studies. The case should be closely monitored in the observation room cautiously as there is chance of hypertension, hypotension or hypoglycaemic episodes; though no such incidence was occurred in our case. The incidence of hypertension is 50% after resection of pheochromocytoma as elevated catecholamine levels persist for 7 to 10 days and hypoglycaemia may occur due to elevated level of insulin because of suppression of beta cells of pancreas.

**CONCLUSION:** Pre-operative preparation, adequate control of hypertension, hypotension and correction of hypovolemia during anaesthesia may reduce the mortality while surgically resecting pheochromocytoma. The combined spinal and general anaesthesia may be good.
