COMPARISON OF STANDARD URINE ANALYSIS WITH URINE DIP STICK TO DETECT URINARY TRACT INFECTION IN CHILDREN
Suresh P1, Antony Jenifer J2, L. Umadevi3, Rathinasamy M4

HOW TO CITE THIS ARTICLE:

ABSTRACT: AIM: To Provide a prospective comparison of the rapid screening tests abilities (Standard urinalysis, Urine dipstick test) to detect UTI in children with suspected UTI, admitted to a tertiary care hospital. MATERIALS & METHODS: All children ≤12 yrs. of age, admitted with suspected urinary tract infection were included in the study. It is a Prospective, comparative study with a sample size of 500 cases. RESULTS: The epidemiological indices - sensitivity, specificity and predictive values of the rapid screening tests (The standard urine analysis, enhanced urine analysis, urine dipstick test) were calculated individually for bacteriuria, pyuria, both and compared with a positive urine culture as the validating standard. CONCLUSIONS: All the rapid screening tests had low sensitivity (<70%) with similar positive predictive values. So no rapid test can screen accurately for UTI in young children. Hence urine culture, the gold standard for diagnosis should be sent if UTI is suspected.

KEYWORDS: UTI, standard urinalysis, urine dipstick.

INTRODUCTION:
AIM: To provide a prospective comparison of the rapid screening tests abilities (Standard urinalysis, Urine dipstick test) to detect UTI in children with suspected UTI admitted to a tertiary care hospital.

MATERIALS & METHODS: This study was conducted in pediatric OPD, at chettinad hospital and research institute, Chennai. All children ≤ 12 yrs. of age, admitted with suspected urinary tract infection were included in the study. Children with Extra-renal focus of infection, previous antibiotic exposure, Pre-existing urinary tract anomalies, recurrent urinary tract infection were excluded. A clean–catch midstream urine specimen, from these children was subjected to the standard urine analysis and urine dipstick testing, along with urine culture.

As per routine clinical practice, the urine specimens were sent to the hospital lab in sterile containers. Urine for culture was refrigerated if not plated within 10 minutes of receipt. Technologists in the hematology laboratory performed the dipstick, standard urinalysis, while the microbiology staff performed the urine culture and gram stain.

It is a Prospective, comparative study with a sample size of 500 cases. The epidemiological indices - sensitivity, specificity and predictive values of the rapid screening tests (The standard urine analysis, enhanced urine analysis, urine dipstick test) were calculated individually for bacteriuria, pyuria, both and compared with a positive urine culture as the validating standard.

Also paired comparisons were made between the tests using Mc Nemar statistic and the chi – square results, p-value calculated. The difference between the two tests was taken as statistically significant if chi – square result is ≥ 3.841 (p – value < 0.05).
RESULTS: A total of 510 children admitted to the hospital with suspected UTI were enrolled in the study, out of which 287 children were males and 223 were females. Around 60% of the children enrolled were in the <3 year age group, 20% in 3-6 year age group and the remaining in 6 - 12 year age group.

All the rapid screening tests had low sensitivity (<70%) with similar positive predictive values. Standard urine analysis had a higher sensitivity than dipstick. Though dipstick test was less sensitive in detecting bacteriuria / pyuria, it was more specific than standard urine analysis. Urine dipstick had higher predictive values and fewer numbers of false positives / false negatives than standard urine analysis.

TABLE 1: COMPARISON OF THE SCREENING TESTS USING EPIDEMIOLOGICAL INDICES

THE McNEMAR TEST: Mcnemar’s test, introduced in 1947 is another useful statistic tool to test marginal homogeneity in 2×2 tables. It is applied to 2 × 2 contingency tables with a dichotomous trait with matched pairs of subjects.

The McNemar statistic is calculated as:

\[ X^2 = \frac{(b - c)^2}{(b + c)} \]

Statistical significance is determined by evaluating the probability of \(X^2\) with reference to a table of cumulative probabilities of the chi-squared distribution. The marginal frequencies are not homogeneous if the \(\chi^2\) result is significant (p < 0.05). When paired comparison was made between these three tests, significant statistic difference (p-value < 0.05) was noted between the standard UA Vs. urine dipstick groups.

TABLE 2: PAIRED COMPARISON OF THE SCREENING TESTS USING McNEMAR TEST:
DISCUSSION: Urinary tract infection (UTI) is recognized increasingly as a common cause of fever in young children.\(^1\) Previous studies of the prevalence of UTI among children presenting to an emergency department with fever found rates ranging from 3.5 to 5.5%.\(^2\) The overall prevalence of UTI observed in this study 17%, was higher than in previous studies.

The highest prevalence was found in the 0-3 year age group (20.46%). There was a slight male preponderance in the 0-3 year age group (1.13:1) and female preponderance thereafter (2.25:1). This is akin to the observation made by various studies in this regard.\(^3,\)\(^4\) This distribution is in keeping with the general finding that male infants have a higher incidence of UTI due to incomplete voiding, uncircumcised status.\(^5,\)\(^6,\)\(^7\) With the progress in age, the female children have a higher frequency of infection due to proximity of urethral and anal opening with the introitus serving as reserve camp.

STANDARD URINALYSIS: Despite the knowledge that the results of manual microscopy are highly variable & are laboratory / technician dependent, it is still widely used as a screening test for UTI. In our study, pyuria was defined as at least 5 WBCs per HPF and bacteriuria as presence of any bacteria per HPF on a centrifuged urine specimen. Bachur et al in his study noted that sensitivity of standard urinalysis is limited to around 80% & does not vary with age in febrile children.\(^8\)

Lin et al in his study involving 162 febrile children < 8 weeks of age concluded that ESR, CRP, Standard microscopy were all imperfect tools in discriminating UTI.\(^9\) Armengol et al, in his study compared the results of standard microscopy with urine dipstick test and observed that standard microscopy has limited usefulness in screening for UTI, owing to its low sensitivity and specificity.\(^10\) In our study, standard urinalysis had a low sensitivity (61.3%) with similar specificity (88.1%). It also had a positive predictive value of 51.9%, the lowest among the three screening tests and the highest percentage of false positives.

URINE DIPSTICK TEST: A urinalysis with manual dipstick is commonly ordered on most children presenting with urinary symptoms. A urine dipstick tests for specific gravity and pH, as well as the presence of urobilinogen, ketones, glucose, hemoglobin, leukocyte esterase and nitrite. In our study using Urinary dipsticks (Multistix 10SG, Bayer Diagnostics), Moderate (2+) or large (3+) leukocyte esterase activity was taken as evidence of pyuria and positive nitrite test was taken as an indicator of bacteriuria. Kathy et al's comparative study on screening tests for UTI concluded that the urine dipstick plus culture tests was the most cost-effective strategy for screening UTI in febrile young children in the emergency setting.\(^11\)

Zaman et al in his study involving 420 hospital inpatients concluded that urine dipstick test had very low sensitivity as well as high false positivity rates and hence not a suitable screening test for UTI.\(^12\) Recently, a Meta-analysis on the diagnostic accuracy of urine dipstick involving 70 publications over 10 years demonstrated that the urine dipstick test alone was useful in all populations to exclude the presence of infection if the results of both nitrites and leukocyte-esterase were negative.\(^13\) In our study, urine dipstick test had the lowest sensitivity (57.9%) but specificity (92.1%) and positive predictive value (60.7%) were comparable to standard urine analysis.

COMPARISON OF THE SCREENING TESTS: The most cost effective strategy was to perform cultures on all infants and begin presumptive treatment on those who had positive dipstick results. Miranda et
al's survey comparing standard urinalysis with urine dipstick test revealed that the sensitivity, specificity and predictive values of the pyuria, bacteriuria by microscopy and leukocyte esterase by reactive strip were comparable.\textsuperscript{14} The Meta analytic study concluded that both Gram stain and dipstick analysis for nitrite and Leukocyte Esterase perform similarly in detecting UTI in children and are superior to microscopic analysis for pyuria.\textsuperscript{15}

**CONCLUSIONS:** Children less than 3 years of age were more susceptible to UTI than older children. There was a slight male preponderance (1.13:1) in the 0-3 year age group and female preponderance (2.25:1) thereafter. This is because of the fact that male infants have a higher incidence of UTI due to incomplete voiding, uncircumcised status. All the rapid screening tests had low sensitivity (<70%) with similar positive predictive values. So no rapid test can screen accurately for UTI in young children.

Hence urine culture, the gold standard for diagnosis should be sent if UTI is suspected. Standard urine analysis had a higher sensitivity than dipstick. Though dipstick test was less sensitive in detecting bacteriuria / pyuria, it was more specific than standard urine analysis. Urine dipstick had higher predictive values and fewer numbers of false positives / false negatives than standard urine analysis.
